I. INTRODUCTION

The UKISS computer model was developed in 1981 by the SFWMD to simulate the operation of the Upper Kissimmee Chain of Lakes, Florida. The model serves as a management tool to predict the lake conditions so that alternative management schemes, aimed at achieving specific objectives, can be evaluated.

The model area covers a chain of nine lakes (Lakes Alligator, Myrtle, Hart, Gentry, East Tohopekaliga, Tohopekaliga, Cypress, Hatchineha, and Kissimmee) in the upper portion of the Kissimmee River Basin. The lakes are interconnected with canals and outlet control structures that are rigidly regulated (Figure 1). The lake discharges are affected by tailwater conditions and the watershed inflows to the lakes are poorly defined. The hydrologic and hydraulic conditions are unique and at the time of the model's development, existing routing models were inadequate to handle the unusual conditions.

II. MODEL OVERVIEW

The Upper Kissimmee Chain of Lakes Routing Model (KROUTE) is a continuous simulation model designed to simulate the operation of the lake system in the Upper Kissimmee River Basin. The study area covers Lakes Alligator, Myrtle, Hart and Mary Jane, Gentry, East Tohopekaliga and Tohopekaliga, Cypress, Hatchineha, and Kissimmee. The model is capable of simulating the management of the system according to predetermined regulation schedules, structure operational criteria, and rainfall conditions.

Level pool storage routing is used to route the flow through the system. Storage routing is similar to a water budget computation. Both use the same mass balance equation:

$$Q_{in} + Q_{lake} - Q_{out} + P - E + DSTOR + ADJ = 0$$

Where

Q_{in} = Structure inflows from upper lake

 Q_{lake} = Watershed inflows

Q_{out} = Structure outflow to lower lake

P = Lake precipitation

E = Lake evaporation

DSTOR = Change in lake storage

ADJ = Inflow adjustment (all unestimated flows and errors of water budget).

In the water budget computation, all components except ADJ in Equation 1 are known historical data. Equation 1 is used to quantify the unknown term, ADJ, so as to evaluate the uncertainties of the water budget.

In storage routing, all components are unknown except rainfall, which is predetermined. Evaporation, E, and watershed inflows, Q_{lake} , are estimated as a function of rainfall. In lakes where the inflows are adequately gaged, ADJ is nearly zero and can be neglected; otherwise ADJ must be estimated or included in the watershed inflow term Q_{lake} . The structure inflow term, Q_{in} , is Q_{out} in the next upstream lake from the previous routing step. Equation 1 is used to determine the unknown quantities Q_{out} and DSTOR; but since both unknowns are a function of the lake stage, lake stage is the only real unknown.

Routing is performed in daily time steps beginning from the uppermost lake (Lake Alligator) to the lowermost lake (Lake Kissimmee). The lake outflow term, Q_{out} , is affected hydraulically by the lower lake stage (backwater effect), and management constraints described by the lake regulation schedules and gate operation criteria. Due to backwater effect, an iteration technique is used to balance the headwater and tailwater stage relationship because the tailwater stage in the current time step is unknown.

Watershed inflows to the lakes are estimated as direct runoff and base flow. Direct runoff is estimated by a District modified Soil Conservation Service method. Base flow is estimated by an empirical formula which relates potential base flow to actual base flow using water table depth as a dependent variable. Both direct runoff and base flow are dependent on the water table depth. A soil moisture accounting procedure was developed to continuously predict the effective water table elevation.

The model provides three operational modes: "simulation," "calibration," and "forecasting." The three modes differ in the way the lake inflows are obtained. In "simulation," historical rainfall and watershed inflows are input. The model simulates the structure flows and stages and is suitable for evaluating situations where only the management variables change. In "calibration," historical rainfall is input and all other flows are predicted. An optimization option is provided to assist in calibrating the parameters. In "forecasting," rainfall is specified and the model predicts all inflows as a function of rainfall.

Complimentary to the routing program (KROUTE) are a water budget computation program (KBUDGET) and a plotting program (KPLOT). The water budget program is used to verify the historical data and to preprocess the input data files needed to calibrate the routing program.

The Windows implementation of the SFWMD computer model (UKISS-WIN) incorporates both KBUDGET and KROUTE in a single executable program. KPLOT and Input/Output will be replaced by VB (Visual Basic) or MS-Access graphing utilities.

Calibration of the model involves the calibration of the watershed parameters. In short term forecasting the results are good; in long term forecasting moderately large deviations at times are observed. The major uncertainty of the model lies in the difficulties of accurately forecasting the watershed inflows.

III THEORETICAL ASSUMPTIONS AND LIMITATIONS

Major assumptions and limitations of the model are presented below.

- 1. A primary assumption of the routing model is that level pool conditions exist. The assumption is valid as long as the flow through the lake is small relative to the storage. The assumption is reasonable under normal flow conditions but is slightly violated under heavy discharge conditions.
- The model simulates the management of the system according to a set of management rules. These rules are expressed in regulation schedules, gate operation criteria, and established rules governing the operation of the structures. As long as the operation follows the established rules, the simulation of the management is possible. Under unusual conditions, the operation may differ from the established rules and thus explains the inability of the routing model to simulate those events.
- 3. The model runs in daily time steps and generates daily average flows and stages. The time step resolution is adequate for most applications except for extreme storm events where instantaneous peak stages and flows are important. Nevertheless, an examination of the recorded lake hydrographs suggests that, due to the large size of the lakes, the instantaneous stages are not significantly different from the daily averages. The errors introduced are probably small in comparison to random fluctuation of the lake stages due to wind effects and other disturbances.
- 4. For certain applications where only the management variables change, historical rainfall and inflow data are used. The implicit assumption is that a change in the management will not change the historical hydrologic variables.
- 5. In forecasting applications, rainfall is specified to be uniformly distributed over time and space for the month of forecast. This is a scenario, rather than a model assumption, and can be modified. The assumption is more acceptable for dry than for wet conditions.

IV. DESCRIPTION OF THE MODEL STUDY AREA

The model covers a nine-lake system in the upper portion of the Kissimmee River Basin. The lakes are interconnected with canals and control structures that are rigidly regulated. Alligator Lake is the uppermost lake with no definable surface water inflows. Outflow from Alligator Lake can be made north through a chain of small lakes to East Lake Tohopekaliga, or south through Lake Gentry to Lake Cypress; however, because of the limited capacity of the lakes north of Alligator Lake, discharges have been made primarily south.

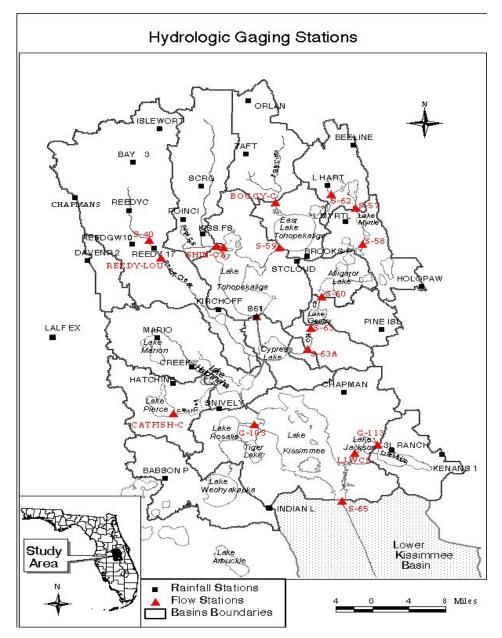

Figure 1. Hydrologic Station Map

North of Alligator Lake (which includes Lakes Alligator, Brick, Coon, Trout, Center and Lizzie) are the Lake Myrtle-Preston system (which includes Lakes Joel, Preston and Myrtle) and the Lake Hart-Mary Jane system, and to the south is the Lake Gentry system. These systems consist of one to five small lakes, and together they make up the headwater portion of the chain. As a group, these small lakes generate only a small portion of the flow in the chain and their influence in the lower lakes is relatively small.

East Lake Tohopekaliga is the first of five major lakes in the chain. The largest inflow to East Lake Tohopekaliga is from Boggy Creek. Second largest is the inflow from Lake Hart through S-62. East Lake Tohopekaliga discharges to Lake Tohopekaliga, which is the second largest lake in the chain. Shingle Creek, which drains to Lake Tohopekaliga, is the largest tributary in the chain.

Lake Cypress receives inflows from both Lake Tohopekaliga and Lake Gentry. There is a stage drop of approximately ten feet between Lakes Gentry and Cypress; and Structures 63 and 63A are used to step down the pools. Lakes Cypress, Hatchineha, and Kissimmee constitute the lower three lake system. They can be considered as a system because their stages tend to be equalized since there are no restricting structures in the connecting canals (C-36 and C-37). At times of high stage, the lower three lakes are connected by swamps, making it difficult, to identify the boundaries.

Reedy Creek is the largest tributary inflow to the lower three lake systems. Reedy Creek splits into two branches near Lake Cypress. One branch enters Lake Cypress and the other, known as Dead River, enters Lake Hatchineha. The major portion of the flow (approximately 70%) enters Lake Hatchineha. Catfish Creek, which connects Lake Pierce with Lake Hatchineha, is another important tributary to the lower three-lake system. Lake Hatchineha also receives inflow from Marion Creek and London Creek from the north, which drains a moderately large area undergoing intensive urban development.

Lake Kissimmee is the largest lake in the chain. Four other medium sized lakes drain into Lake Kissimmee, including Lake Rosalie, Lake Tiger, Lake Marian, and Lake Jackson. With the exception of Lake Tiger, however, these lakes contribute little flow to Lake Kissimmee because earth dams were constructed at their outlets. Inflows from the drainage areas of the lower three lakes, though important, are poorly gaged.

The Kissimmee Chain of Lakes are shallow; average depths range from 13 ft in Lake Alligator to 8 ft in Lake Kissimmee. Geologically, the lakes cut into the surficial aquifer, which has a thickness ranging from 50 to 100 ft in the study area. The surficial aquifer is made up of a relatively homogeneous silty fine to medium sand. Permeability is estimated to be low. Although direct seepage to the lake is normally small in comparison to other inflows, at time of drought, seepage may become important.

V. DESCRIPTION OF MODEL COMPONENTS

A. Control Structure Characteristics

The Kissimmee Chain of Lakes is interconnected with canals and discharge control structures that are rigidly regulated. The control structures consist of gated culverts and gated spillways

and are summarized in Table 1. Several structures have special operational characteristics and require special treatment.

Lake Alligator has two outlet structures. At the north end is the S-58 gated culvert, and at the south end is the S-60 gated spillway. The S-58 culvert has seldom been used because of the limited capacity of the small lakes and canals north of Lake Alligator. An assumption is made that the S-58 structure will be operated only when the capacity of S-60 is inadequate to lower the stage at Lake Alligator to regulation schedule within a day.

Table 1 – Control Structures Parameters

Structur	Туре	Crest EL MSL	Length	Diamete	Design	Remarks
e		IVISL	(Ft)	r (Ft)	Q (cfs)	
S-57	Culvert	52.5(invert)	80	4.5	170*	Seldom operated
S-58	Culvert	54.5(invert)	70	4.5	160*	
S-59	Spillway	49.1	18	NA	590	Weir below structure
S-60	Spillway	55.0	12	NA	450	
S-61	Spillway	36.9	27	NA	1570	
S-62	Spillway	55.3	14	NA	410	
S-63	Spillway	54.0	15	NA	715	
S-63A	Spillway	49.4	30	NA	2000	Automatic gate
S-65	Spillway	39.3	81	NA	11000**	

Note: * Based on an analysis of the historical data, maximum allowable discharges of 230 cfs and 110 cfs are assigned to S-57 and S-58 as additional operational constraints.

Structure 58 (S-58) is located in C-32, which connects Lakes Trout and Joel about 3700 feet downstream from Trout Lake.

S-58 is a double-barreled corrugated metal pipe culvert with discharge controlled by stem operated vertical lift gates. Operation of the gates is manually controlled in accordance with the seasonal operational criteria.

The culvert structure maintains water control stages in C-32 and Lakes Alligator, Lizzie, Coon, Center and Trout; passes up to 30 percent of the standard project flood; and passes sufficient discharge during low-flow periods to meet irrigation demands downstream.

^{**} The design capacity for S-65 has been increased to 18,000 cfs with added 2 gates in 2001.

During floods the culvert structure is used, together with S-60, to assist in regulating and maintaining water levels from 62.0 ft to 64.0 ft. NGVD, in the lake upstream from the structure as shown on the regulation schedule. The design capacity of the structure is 160 cfs.

To meet structural stability requirements, the maximum allowable hydrostatic head on the structure should not be allowed to exceed 2.0 ft with a headwater elevation of 64.0 ft and a tailwater elevation of 62.0 ft, NGVD.

Structure 57 (S-57) is located in C-30, connecting Lakes Myrtle and Mary Jane, about 6200 feet downstream from Lake Myrtle.

S-57 is a double-barreled corrugated metal pipe culvert, with discharge controlled by stem operated vertical lift gates. Operation of the gates is manually controlled in accordance with the seasonal operational criteria.

The culvert structure is used to maintain scheduled stages in Lakes Myrtle, Preston and Joel upstream from the structure; passes up to 30 percent of the standard project flood; and passes sufficient discharge during low-flow periods to satisfy irrigation demands downstream.

The culvert structure normally maintains seasonal water control stages of from 60.0 to 62.0 ft, NGVD upstream from the structure, as shown on the regulation schedule. When the lake stage rises above schedule and above normal inflows are anticipated, releases up to design capacity of 170 cfs can be made.

To meet structural and stability requirements, the maximum allowable hydrostatic head on the structure should not be allowed to exceed 2.2 ft with a headwater elevation of 59.0 ft, and a tailwater elevation of 56.8 ft, NGVD.

Structure 62 (S-62) is located in C-29 at the outlet of Lake Hart which discharges into Lake Ajay.

S-62 is a reinforced concrete, gated spillway with discharge controlled by a vertical lift gate. Operation of the gate is manually controlled in accordance with the seasonal operational criteria.

The spillway structure is used to maintain scheduled stages in Lakes Hart and Mary Jane upstream from the structure; passes up to 30 percent of the standard project flood, restricts discharge during floods to that which will not cause damaging velocities or stages downstream; and passes sufficient discharge during low-flow periods to satisfy irrigation demands downstream.

The spillway gate should be operated during floods to assist in regulating water levels in lakes Hart and Mary Jane seasonally between 59 to 61 ft, NGVD as shown on the regulation schedule. When the lake stage is over 0.5 feet from the prescribed level, maximum releases can be made. The design capacity of the structure is 640 cfs.

To meet structural and stability requirements, the maximum allowable hydrostatic head on the structure should not be allowed to exceed 7.2 ft with a headwater elevation of 66.6 ft, NGVD and a tailwater elevation of 59.4 ft, NGVD.

Structure 60 (S-60) is located in C-33 between Lakes Alligator and Gentry about 1,500 feet upstream from County Road 534 and 3,700 feet downstream from Alligator Lake.

S-60 is a reinforced concrete, gated spillway with discharge controlled by a stem operated, vertical lift gate. Operation of the gate is manually controlled in accordance with seasonal operational criteria.

The spillway structure maintains desirable water-control stages in C-33 and Alligator Lake; passes up to 30 percent of the standard project flood without exceeding desirable stages; restricts discharge during floods to that which will not cause damaging velocities or stages downstream; and passes sufficient discharge during low-flow periods to maintain stages and satisfy irrigation demands downstream.

The spillway structure normally maintains a seasonal desirable water-control stage of 62.0 to 64.0 ft, NGVD upstream from the structure as shown on the regulation schedule. S-60 and S-58 both discharge from Alligator Lake, consequently discharges from both structures must be considered in establishing release schedules.

The maximum water level differential should not exceed 7 feet with the headwater not exceeding elevation 68.0 ft, NGVD.

Structure 59 (S-59) is located in C-31 between East Lake Tohopekaliga and Lake Tohopekaliga at the outlet of East Lake Tohopekaliga.

S-59 is a reinforced concrete, gated spillway with discharge controlled by a vertical lift gate. Operation of the gate is manually controlled in accordance with seasonal operational criteria.

S-59 is the outlet structure for East Lake Tohopekaliga. The spillway structure normally maintains desirable water-control stages in the lake upstream from the structure; passes up to 30 percent of the standard project flood without exceeding desirable stages; restricts discharges during floods to that which will not cause damaging velocities or stages downstream; and passes sufficient discharge during low-flow periods to maintain stages and satisfy irrigation demands.

Downstream of S-59 a sheet pile weir was constructed to influence the tailwater of the structure. The crest of the weir is elevation 50.83 ft. A submerged weir equation is used in the model to adjust the tailwater stage at S-59 from the lake stage.

To meet structural and stability requirements, the maximum differential hydrostatic head on the structure should not be allowed to exceed 8 feet when the headwater is below 62.8 ft, NGVD. If the headwater should ever exceed 62.8 ft, NGVD, the allowable differential head will be reduced.

Structure 61 (S-61) is located in C-35 at the south shore (outlet) of Lake Tohopekaliga.

S-61 is a reinforced concrete, gated spillway with discharge controlled by a vertical lift gate, and a reinforced concrete lock structure with two pairs of sector gates. Operation of the spillway gate is manually controlled in accordance with seasonal operational criteria.

The spillway structure normally maintains desirable water-control stages in Lake Tohopekaliga upstream from the structure during low-flow periods; passes up to 30 percent of the standard project flood without exceeding desirable stages; and passes sufficient discharge during low-flow periods to maintain stages and satisfy irrigation demands downstream. The lock structure permits passage of vessels with a draft of less than 6 feet between the Kissimmee River (C-38) and Lake Tohopekaliga.

The gate in the spillway should be operated to permit water levels in Lake Tohopekaliga to fluctuate seasonally between 52 ft and 55 ft, NGVD as shown on the regulation schedule.

To meet structural and stability requirements, the maximum differential hydrostatic head on the structure should not be allowed to exceed 10 ft when the headwater is below 55.0 ft, NGVD. When the headwater is between 55.0 and 59.9 ft, the maximum differential head should not be allowed to exceed 6 ft. If the headwater should ever exceed 59.9 ft the allowable differential will be reduced.

Structure 63 (S-63) is located in C-34 about 2000 feet downstream from Lake Gentry.

S-63 is a reinforced concrete gated spillway with discharge controlled by a stem operated vertical lift gate. Operation of the gate is manually controlled in accordance with the seasonal operation criteria.

The spillway structure maintains desirable water-control stages in C-34 and Lake Gentry upstream from the structure during low-flow periods; passes up to 30 percent of the standard project flood without exceeding desirable stages; restricts discharge during floods to that which will not cause damaging velocities or stages downstream; and passes sufficient discharge during low-flow periods to maintain stages and satisfy irrigation demands downstream.

The spillway structure normally maintains a seasonal desirable water-control stage of 59.5 to 61.5 ft, NGVD upstream from the structure as shown on the regulation schedule. When the lake is within 0.5 ft of the schedule, forecasts should be made and releases initiated to return the lake to schedule within 15 days. When the lake stage is considerably above schedule and large inflows are anticipated, releases up to the design capacity of 715 cfs can be made.

Structure 63A (S-63A) is an automatic spillway located below S-63.

Both structures control the outflow from Lake Gentry and together allow a stepped drop of ten feet between Lake Gentry and Lake Cypress. It is assumed that discharges at S-63 and S-63A are the same and therefore only S-63 flow is modeled. Structure 63A maintains, automatically, an optimum headwater pool of 56.5 msl. The model uses this 56.5 msl to calculate the flow through S-63 and is assumed to be unchanged.

Spillway S-65 (S-65) is the outlet of the chain.

S-65 can discharge up to 11,000 cfs. Under actual operation, however, the discharge at S-65 has rarely exceeded 6000 cfs. In day-to-day operations, the District determines the maximum allowable discharge at S-65 based on the amount of inflow experienced on the previous day. Based on statistical analyses of the historical data, two assumptions were made:

First, the tailwater stage at S-65 is fixed at 46.3 msl, which is the historical mean stage maintained by S-65A. The design tailwater elevation (46.3 ft NGVD) will be different after the completion of Kissimmee River restoration projects due to back filling of C-38. Therefore, the tailwater stage at S-65 will need to reflect this change, especially for simulation cases where the simulation duration covers both exiting and restoration conditions.

Second, the maximum discharge at S-65 is limited to 3000 cfs and 5000 cfs, respectively, under dry and wet conditions. These two values are based on past flow through S-65 prior to 1980. With additional flow data and climatic changes in the 1980-90s, the value may not be the same. The model should treat these two values as input and use 3000 cfs and 5000 cfs as default values. Under Kissimmee River Restoration Project, the maximum S-65 discharge has increased up to 18,000 cfs instead of 11,000 cfs. Two additional gates spillways have been added to existing S-65 structure. The probability of ever being able to discharge 18,000 cfs for extended period is remote. Only under an extreme or nearly catastrophic event would there be sufficient head across the structure (ie. Lake Kissimmee stages greater than 56 ft.) to discharge 18,000 cfs to the Low Basin.

Wet conditions are defined as having antecedent monthly rainfall exceeding eight inches. Baffle blocks were installed below S-65 in 1986. The dry condition discharge constraint was raised to 6000 cfs on an interim basis until the model is extended to the lower basin whereby the boundary condition will be shifted from S-65 to S-65E.

B. Regulation Schedules

The lakes are regulated by rigid hard-coded schedules. The regulation schedules represent the management aspect of the system aimed at optimizing flood control, water conservation, and environmental enhancement. The trend of the regulation schedules generally reaches the minimum and maximum at the beginning and end of the wet season to prepare for flood control and water conservation, respectively. Regulation schedules are, nevertheless, subjective rules that change every few years.

In the routing model, the actual regulation schedules for the years under simulation are entered as breakpoint data in a separate input file (TAPE4). Since its original inception the model has been used to develop a new regulation schedule for Lakes Kissimmee, Hatchineha and Cypress to meet some of the requirements for the restoration of Kissimmee River. This new regulation schedule contains a set of complex zones for flow releases and discharge variations with the program code designed specifically for the new regulation schedule for Lake Kissimmee. Any deviation of flow releases at any time during the year requires code changes if the deviations were not originally coded in the model. It is necessary to develop a generic routine capable of handling any possible regulation schedule changes relating the parameters; flow, stage and time for each lake system.

C. Gate Operation Criteria

The maximum allowable gate opening for each spillway is governed by the "Riprap Control" criteria, so named because the objective is to prevent excessive velocity damage to the riprap around the structures. The criteria were established by the US Army Corps of Engineers and presented in charts such as that shown in Table 2. The

family of curves can be fitted by the following equation, which appears to be the same general form of equation used to calculate flow through a weir under submerged conditions.

$$GO = A (HW - TW)^B TW^C + D$$
 <2>

where

GO = Maximum allowable gate opening in ft

HW = Headwater elevation

TW = Tailwater elevation

A,B,C,D = Constant coefficients as shown in Table 2

Table 2 - Riprap Control Coefficients

	A	В	С	D
S-59	0.38x10 ⁻⁸	-0.22083	5.41927	-3.673
S-60	2.2588896x10 ⁻	-0.51706295	8.2136768	0.
S-61	0.002954	15463	2.24833	-10.82
S-62	1.7404157x10 ⁻	59052612	12.743331	0.
S-63	0.022745	21273	1.6471	-8.246
S-65	0.36587777	55682769	.95236956	0.

Gated culvert structures S-57 and S-58 do not have gate operation criteria and this presents difficulties in simulating their operation. Their discharge capacities, however, are relatively small and S-58 has seldom been operated. Based on an analysis of the historical data, maximum allowable discharges of 230 and 100 cfs are assigned to S-57 and S-58 as additional operational constraints.

D. Structure and Canal Flow Equations

The flow equations for the control structures and Canals C-36 and C-37 are summarized in Table 3. Though the flow equations for the structures incorporate all

flow conditions, under normal operation submerged controlled flow predominates. Stream flow gaging data were used to calibrate the spillway flow equations. Since most of the measurements were taken under submerged controlled flow conditions, only this type of flow was calibrated. The fitted coefficients are shown in Table 3. Calibrated values of some coefficients exceeded the theoretical range, which can be attributed to datum errors and other unknown noise in the original data.

Canals C-36 and C-37 are the open channels connecting Lakes Cypress and Hatchineha, and Lakes Hatchineha and Kissimmee. Because there are no control structures along C-36 and C-37, the stages in the lower three lakes tend to be equalized. The flow rating equations for C-36 and C-37 (Table 3) were established from stream flow gaging data taken in 1983 and 1984. The flow equations shown in Table 3 are in essence a Manning Equation using both the stage and water surface slope as independent variables.

$$Q = A (HW - TW)^B (HW - C)^D$$
 <3>

where

Q = Discharge in cfs

HW = Upper lake stage in ft msl

TW = Lower lake stage in ft msl

A.B.C.D = Calibrated coefficients shown in Table 3.

HW = Headwater elevation is mslTW = Tailwater elevation in mslL = Length of pipe in ft

Canal 36 and 37

C-36: $Q = 35.61885873(HW-TW-.19)^{.5511796}(HW-35.07)^{1.6667}$ C-37: $Q = 87.07430164(HW-TW+.12)^{.4976433}(HW-42.12)^{1.6667}$

The rating equations compute the instantaneous flow rate, and since the model runs in daily time steps, there may occasionally be a time resolution problem. In order to assure the conservation of mass, the computed total daily discharge is compared with the allowable storage release (which is estimated as the storage above the regulation schedule plus the expected inflows) and the smaller of the two is selected. If the allowable storage release is less than zero, no discharge will be made. Since there are no control structures in C-36 and C-37, the allowable storage release at Lakes Cypress or Hatchineha is calculated as the storage above the downstream lake stage plus the expected inflows. If the allowable storage release is negative due to higher stage in the downstream lake, reverse (negative) flow is permitted.

In summary, therefore, by combining gate operation criteria (Equation 2), flow rating equations (Table 3), and lake regulation schedules, the management of the system can be simulated.

E. Rainfall and Evaporation

In forecasting, rainfall is a predetermined quantity specified by the user. Evaporation is predicted as a function of rainfall. Both rainfall and evaporation are distributed uniformly throughout the lakes unless specified otherwise. Evaporation is predicted by the following frequency correlation equation:

$$E_d = C\{E_m - (R_m - RN_m)S_E/S_R\}/N_m$$

<4>

where:

 E_d = Estimated daily lake evaporation in inches

C = Pan to lake coefficient (0.8 used as default value)

 E_m = Normal pan evaporation for calendar month, m, in inches

 S_E = Standard deviation of pan evaporation (1.7094 used)

 S_R = Standard deviation of rainfall (2.4755 used)

 R_m = Total rainfall for calendar month m in inches

 RN_m = Normal rainfall for calendar month, m, in inches

 N_m = Number of days in calendar month, m

Assuming both follow the same probability distribution, the above equation equates the frequency occurrence of rainfall and evaporation; that is, a one in ten year rainfall in any month will generate a one in ten year evaporation in the same month. Furthermore, the relationship is inverse; that is, the smaller the amount of rainfall, the greater the evaporation.

Historical rainfall and pan evaporation data were used in model calibration. Rainfall input to the lakes is based on a weighted average rainfall from stations around the lakes as listed in Table 4. The Rainfall stations used to develop average rainfall over each lake are based on available long-term rainfall stations close to the lake. Table 4 is no longer valid due to some of the rainfall stations no longer in service. The data from Table 4a now supercedes that from Table 4.

Evaporation is assumed to be uniformly distributed throughout the lakes in the chain. A 0.8 pan to lake coefficient is used. The 0.8 coefficient was calibrated from a water budget analysis of East Tohopekaliga for the drought period of October 1981 to April 1982, however, further analysis based on 30 years of water budget data has indicated that a different value should be used. Therefore, this value will be an input data and use 0.8 as default value.

Table 4 – Rainfall Station Weighting Factors

F. Watershed Inflows

Some modifications were made to the watershed inflow calculations. The modification had to do with the way the model computed daily runoff from the various sub-basins. The inflow module consists of a set of routines that will compute runoff, at daily time steps, over a long period. For each time step, the required daily data is supplied to the inflow routine. The routine will use the data to maintain a soil moisture balance for the basin, and compute the depth of surface runoff for the current time step.

For the purposes of this document, the module is divided into four parts:

- 1. Soil moisture balance,
- 2. Computation of surface runoff,
- 3. Computation of ET, and

4. Miscellaneous computations.

Soil Moisture Balance:

The soil moisture balance is very much like that used by Fan (1986). The main difference is the computation of ET. Computing a soil moisture deficit, for each time step performs the balance:

$$SMD_I = SMD_{I-1} + ET + B_f - [P - R_o]$$

Where:

 $SMD_I = soil moisture deficit, in inches, for time step I;$

ET = evapotranspiration, in inches;

B_f = base flow or seepage, in inches;

P = precipitation, in inches; and

R_o = excess rainfall, in inches;

Estimation of ET is discussed below. The base flow term, B_f, is computed using

$$B_f = [K_{bf}/H_{max}] \{H_{max} - SMD/12n\}$$

Where:

K_{bf} = a coefficient representing the maximum rate at which the water can fall, inches per time step;

n = soil porosity, inches per inch; and

 H_{max} = water table depth below which base flow ceases, feet;

When the water table depth, given by SMD/12n, is less than H_{max} . However, if the water table depth is greater then H_{max} , base flow is zero.

Excess rainfall, R_o , is estimated using the SCS runoff equation using the soil moisture deficit as the available storage:

$$(P - 0.2SMD)^2$$
 $R_0 = ----- P + 0.8SMD$

Surface Runoff Computation:

Fan (1986) assumed that during a time step surface runoff was equal to the excess rainfall, R_o , as calculated above. This yields large peak outflows of very short duration. This module uses an imaginary linear reservoir to compute instantaneous outflow rates at the end of each time step:

where:

 Q_I = runoff rate, in inches per hour, at the end of time step I;

 Δt = time step, in hours (usually 24); and

 K_{ro} = linear reservoir routing coefficient, in hours;

The value return by the module routine is the runoff depth, O, in inches, for the time step, or

• =
$$\Delta t \{ (Q_1 + Q_{1-1})/2 \}$$

Evapotranspiration Computation:

Evapotranspiration is estimated using the methodology implemented and used by the CREAMS model (Knisel, 1980). This method is a modified form of the Ritchie method (Ritchie, 1972). The modifications made to the Ritchie method are not extensive, but they are important. The CREAMS manual by Knisel provides only limited documentation of the method.

The inflow module uses a truncated form of the Penman equation to estimate potential evapotranspiration. In this form, the radiation term is simplified and the advection term is ignored:

$$ET_p = 1.28 \Delta H_o [\Delta + \Gamma]$$

Where:

ET_p = potential evapotranspiration, in millimeters per day;

 Δ = change in saturation vapor pressure with temperature,

=
$$T_{K}$$
 = T_{K}^{2} exp[(21.255-5304)/ T_{K}]

 T_K = mean daily temperature, in degree Kelvin;

 Γ = the psychrometric constant or 0.68;

 H_o = net radiation or $(1 - \alpha)R_{so}/58.3$;

 α = crop albedo or = 0.23

R_{so} = total (long-wave) incoming solar radiation, in calories/cm;

1.28 = a constant to convert calories per square centimeter to inches of water per day.

Actual ET is estimated as the sum of two components; soil evaporation and plant ET. Estimation of soil evaporation is a complicated algorithm. Ritchie (1972) presented a flow chart of the procedure, which is probably the best description available. The estimation is based on the concept of soil evaporation having two "stages": (1) early after rainfall, when surface soil layers are relatively wet, and (2) after topmost soil layers are dry. In stage 1, there is little resistance so soil evaporation proceeds at a potential rate:

$$ET_p \; exp(\text{-0.4LAI}\;) \quad for \;\; K_{wc} \; >= \; exp\; (\text{-0.45LAI}\;)$$

$$E_s \;\; = E_{sp} \;\; = \;\; ET_p \;\; K_{wc} \qquad for \quad K_{wc} \;\; < \;\; exp\; (\text{-0.4LAI}\;)$$

Where:

 E_{sp} = potential soil evaporation, mm/day;

LAI = leaf area index; and

 K_{wc} = "winter cover factor"

Inclusion of the "winter cover factor" is one of the major differences between the Ritchie method presented by Ritchie and that used in the CREAMS model. The factor is retained in the runoff module.

"Stage 2" soil evaporation begins when a specified amount of "stage 1" evaporation has occurred. This upper limit of stage 1 evaporation is given by Knisel (1980) as

$$U = 9.0 \exp[\alpha_s - 3.0]$$

Where:

U = upper limit of stage 1 soil evaporation, mm;

 α_{s} = a soil coefficient = 4.5 for loamy soils, 3.5 for clay soils, 3.3 for sandy soils.

The module currently sets α_s to 3.3 for sandy soils; this can be changed at runtime.

Stage 2 soil evaporation is estimated using a decay function, where the evaporation rate is a function of time

$$\mathsf{E}_{\mathsf{s}} = \alpha_{\mathsf{s}} \left[\sqrt{\mathsf{t}} - \sqrt{(\mathsf{t} - \mathsf{1})} \right]$$

Where: t is time, in days, since stage2 soil evaporation started.

Plant evapotranspiration is estimated using the equation:

$$\begin{split} \text{ET}_{\text{plant}} &= \text{[LAI/3] ET}_{\text{p}} \quad \text{for LAI} \; \leq \; 3.0 \\ &\quad \text{ET}_{\text{p}} \; - \; \text{E}_{\text{s}} \quad \text{for LAI} \; > \; 3.0 \end{split}$$

The estimate of total ET is the sum of plant ET and soil evaporation, or potential ET if it is less than the sum.

Miscellaneous Computations:

Fitting Monthly Data. The inflow module is generally used for daily estimations of runoff, so daily temperature, radiation and leaf area index must be supplied to the module. Unfortunately consistent daily values of these quantities are rarely available, but monthly values may be more available. Sets of routines, which will form daily estimate temperature, radiation, and leaf area index from available monthly values are contained in the module.

Given twelve monthly values the forfit routine will fit a truncated Fourier Series of the form

$$X_1 = a_0 + a_1 \sin(c_1) + a_2 \cos(c_1)$$

Where:

I = Julian day;

 X_{l} = daily value for day I;

$$C = 0.017167$$
;

And a_0 , a_1 , and a_2 are coefficients estimated from the monthly data as

$$a_0 = 1/12 \sum_{m=1}^{12} X_m$$

$$a_1 = 2/12 \sum_{m=1}^{12} \cos [X_m/12]$$

$$a_2 = 2/12 \sum_{m=1}^{12} \sin [X_m/12]$$

where:

 X_m = mid month (or monthly mean) value for month m.

Thirteen watersheds are simulated in the model. There are four gaged (Boggy Creek, Shingle Creek, Catfish Creek, and Reedy Creek) and nine ungaged watersheds. Each ungaged watershed represents a combination of several local watersheds that drain to a lake. Watershed inflows in the lakes consist of both direct runoff and base flow. In continuous simulation, base flow can be more important than direct runoff because it occurs continuously. The model simulates direct runoff and base flow separately.

Direct runoff is simulated by a District-modified Soil Conservation Service Direct Runoff Formula. Routing of the direct runoff (rainfall excess) is not performed because the watershed time of concentrations are smaller than a one day time step.

$$Q = (P-0.2S)^{2}$$
(P+0.8S) <5>

where

Q = Direct runoff volume in inches

P = Precipitation in inches

S = Soil moisture deficit in inches

Base flow simulation is based on the concept of potential and actual base flow. The actual base flow is linearly related to the water table depth.

$$B = SCOEF (HMAX-WT)$$
(HMAX) <6>

where

B = Base flow in inches

SCOEF = Potential base flow in inches

HMAX = Depth at which base flow ceases (5 to 10 ft)

WT = Water table depth

In the above equation *SCOEF* represents the potential base flow when the water table is near the land surface; *HMAX* represents the effective depth at which the base flow ceases. This corresponds to a situation when the water table has effectively fallen below the streambeds. The formulation of the base flow is analogous to the formulation of the watershed evapotranspiration loss.

$$ET = PET (ROOT-WT)$$

$$(ROOT)$$
<7>

where

ET = Watershed evapotranspiration in inches

PET = Potential ET in inches = PCOEF x EVAP

PCOEF= Pan coefficient at PET (0.7 to 0.9)

EVAP = Pan evaporation in inches

ROOT = Deep root zone in feet below which ET ceases (5 to 10 ft)

WT = Water table depth in feet

To evaluate Equations 5, 6 and 7 the knowledge of the water table depth WT and soil moisture deficit S is needed. Assuming a constant storage coefficient of 0.2 and including a unit conversion factor, the water table depth WT (in feet) can be related to S (in inches) by a factor of 2.4. Thus only S needs to be quantified. A soil moisture accounting procedure is formulated to continuously monitor S.

$$S_t = S_{t-1} + ET - P + Q + B$$
 <8>

where

 S_t = Soil moisture deficit (in) at time step t

 S_{t-1} = Soil moisture deficit (in) at previous time step, t-1

ET = Watershed evapotranspiration loss in inches from Equation 7

P = Precipitation in inches

Q = Direct runoff in inches from Equation 5

B = Base flow in inches from Equation 6

In summary, the watershed discharge is modeled as the summation of direct runoff and base flow from Equations 5 and 6 which, in turn, are functions of the soil moisture deficit *S* determined by Equations 7 and 8. The procedure described requires the calibration of four parameters: *SCOEF*, *HMAX*, *PCOEF* and *ROOT*. The base flow parameters (*SCOEF* and *HMAX*) are primarily a function of the drainage density and aquifer characteristics; the *ET* parameters (*PCOEF* and *ROOT*) are primarily a function of the land use and soil type. An optimization procedure is provided to assist in calibrating the parameters and is described below.

The current approach is a lumped parameter approach; that is, each watershed is treated as a unit and the parameters are effective parameters for the entire watershed. Thus, although the procedure is physically based and has the ability to reflect changes in the physical conditions, statistical elements are introduced in the process of calibration and the procedure can only be viewed as partly deterministic.

G. Stage-Area /Stage Volume Relationships

Polynomial equations were fitted to the stage-area and stage-volume data and the coefficients are shown in Table 5. Polynomial fitting is suitable for interpolation only; extrapolation beyond the range of data used to calibrate the equation can be erroneous. The following linear extrapolation equation is used to project the area above the maximum surveyed stage.

$$AREA = A_{(hmax)} + DA_{(hmax)} x [h-hmax]$$
 <9>

where

AREA = Lake area in acres

 $A_{(h)}$ = Stage area function

 $= D1(h)^4+D2(h)^3+D3(h)^2+D4(h)+D5$

h = Stage in ft msl (>hmax)

D1 to D5= coefficients for area rating

 $DA_{(h)} = dA_{(h)}/dh$

 $= 4(D1)(h)^3+3(D2)(h)^2+2(D3)(h)+D4$

hmax = Maximum stage used in polynomial fitting in ft msl

Similarly, linear extrapolation is used to project the volume above the maximum surveyed stage using the following equation.

$$VOL = V_{(hmax)} + (AREA + AREA_{(hmax)})/2 [h-hmax]$$
 <10>

where

AREA = Lake area in acres (from equation 9)

VOL = Lake volume in acre-ft = Stage volume function $V_{(h)}$

= C1(h)⁴+C2(h)³+C3(h)²+C4(h)+C5

h = Stage in ft msl (>hmax)

C1 to C5= coefficients for area rating

hmax = Maximum stage used in polynomial fitting in ft msl

Table 5 – Stage-Area/Stage-Volume Relationships

AREA =
$$D1(h)^4 + D2(h)^3 + D3(h)^2 + D4(h) + D5$$

VOL = $C1(h)^4 + C2(h)^3 + C3(h)^2 + C4(h) + C5$ <12>

where

AREA = Lake area in acres VOL = Lake volume in acre-ft

h = Stage in ft msl
C1 to C5 = coefficients for stage volume rating
D1 to D5 = coefficients for stage area rating

hmax = Maximum stage used in polynomial fitting in ft msl Minimum stage used in polynomial fitting in ft msl hmin

For projection below the minimum surveyed stage, the following equations are used. The formulation is empirical and the objective is to avoid negative area projection.

$$AREA = A_{(hmin)} \times (h/hmin)^{1.5}$$

$$VOL = V_{(hmin)} \times (h/hmin)^{1.5}$$

where

AREA = Lake area in acres

VOL = Lake volume in acre-ft

 $A_{(h)}$ = Area function

 $V_{(h)}$ = Volume function

h = Stage in ft msl (<hmin)

hmin = Minimum stage used in polynomial fitting in ft msl

When using regression equations, especially those with large coefficients, it is important to take into account the numerical resolution of the compiler. Using 4 byte precision the numerical accuracy is approximately X $\pm 2^{-22}$. (All compilers conforming to the IEEE floating point standard will uphold this approximation.) To demonstrate by example:

say, for Lake Alligator

Stage = 63.83

D1 = -22.3861

D2 = 5641.0255

D3 = -532464.04

D4 = 22314593

D5 = -350337540

then

Stage = $63.83 \pm 0.000003814697265625000$ D1 = $-22.3861 \pm 0.000001907348632812500$

etc...

and the Area calculated using equation 11 is a value between 7065.255 and 8211.165. To the compiler these values are indistinguishable. (In this particular example the compiler returned a value of 7638.21 versus the actual value of 7830.916.)

The raw data was examined by comparing the measured areas with those calculated from the polynomial coefficients. The measured volume was also compared with the volume calculated from the polynomial coefficients and also with the volume calculated using equation 13.

 $VOL = h/3 (A1 + A2 + sqrt(A1 \times A2))$ <13>

where

VOL = Lake volume in acre-ft

h = Lake stage

A1 = Lake area in acres at stage 1

A2 = Lake area in acres at stage 2

The polynomials obtained from regression analysis generally provided good correlation with the measured data. The major errors would appear to be due to rounding errors in the manual calculation of the (measured) volume. Table 6 below shows the error (in %) comparing the measured area to that calculated from the polynomial coefficients and also the error comparing the volume calculated using equation 13 with the measured volume and the volume calculated from the polynomial coefficients.

Table 6 – Area and Volume Percentage Error

	Area Min. Error	Area Max Error	Area Ave. Error	Measured Volume Min. Error	Measured Volume Max. Error	Measured Volume Ave. Error	Polynomial Volume Min. Error	Polynomial Volume Max. Error	Polynomial Volume Ave. Error
Alligator	-16.4	10.1	-0.21	0.0	1.1	0.42	-3.1	1.3	0.27

Hart	-0.8	0.3	-0.04	-0.4	1.1	0.04	-0.2	0.2	0.00
Gentry	-1.2	1.8	-0.08	0.0	0.7	0.24	-0.0	0.9	0.22
E. Toho	-1.5	1.1	-0.31	-0.6	0.2	-0.14	-2.4	0.2	-0.96
Toho	-1.4	0.8	-0.19	-0.2	0.5	0.12	-1.2	0.6	0.12
Cypress	-10.8	8.1	1.55	-0.6	1.9	0.43	1.5	6.2	3.61
Hatchineha	-62.3	15.1	-11.47	0.0	2.9	0.83	1.5	63.7	11.72
Kissimmee	-27.8	3.1	-0.13	-2.55	0.40	-0.03	2.1	10.0	3.85

This analysis suggests that although the polynomial fit is adequate in most cases, the magnitude of numerical error able to be introduced within the compiler reduces modeling confidence to the point where consideration should be given to replacing the stage-area and stage-volume function with a simple linear interpolation routine.

The lack of either, the original raw data used to generate the rating curves for the lake discharge structures, or the availability of the data in electronic form, makes a rigorous analysis futile. Errors are introduced interpolating data from the graphs provided, which make a statistical analysis worthless. However a number of spot-checks of the results for each discharge structure has shown the results generated by the software appear to fall on the curves provided. This procedure does not suffer from the same compiler-introduced residual errors, however consideration should still be given to replacing the Gate Operation Criteria (equation 2) with a similar interpolation routine to that suggested for the stage/volume relationship. This would allow for the user to modify the discharge relationship without the need to modify source code.

H. Routing Procedures

Routing proceeds from the uppermost lake (Alligator) to the lowermost lake (Kissimmee) by solving the mass balance equation in daily time steps. The mass balance equation is rewritten below with the unknowns placed on the left side of the equation.

$$DSTOR+Q_{out} = Q_{in}+P-E+ADJ+Q_{lake}$$
 <14>

where

 Q_{in} = Inflows from upper lake structure

 Q_{lake} = Watershed inflows

P = Lake precipitation

E = Lake evaporation

ADJ = Inflow adjustment term - all un-estimated flows and errors of water

budget

DSTOR= Change in lake storage

 Q_{out} = Outflow to lower lake

The model can operate in three different modes. Each routing mode differs in the way the terms on the right side of Equation 14 are determined:

- **Simulation Mode:** All terms on the right side of Equation 14 are input from historical records. The model routes the flow through the lakes and simulates only the management aspect of the system. In other words, the model predicts the structure flows and lake stages based on historical hydrologic input. This mode is suitable for evaluating situations where only the management variables change, such as in evaluating a change in the regulation schedules. The implicit assumption is that a change in the management variables will not affect the historical hydrologic variables.
- Forecasting Mode: All terms on the right side of Equation 14, except rainfall, are predicted
 using rainfall as a conditional dependent variable. Rainfall is predetermined. Variation of
 the management rules, such as the regulation schedules, can also be input as additional
 conditional variables. This mode is most general, as the ultimate objective of a routing
 model is to be able to forecast under any conditions.
- Calibration Mode: This mode is essentially the same as the previous one except that
 historical rainfall is used. This mode is used to calibrate and verify the forecasting capability
 of the model by comparing historical to model results. An optimization operation is provided
 to aide in the calibration of the parameters.

On the left side of Equation 14, the unknowns DSTOR and Q_{out} are both a function of the lake stage and thus stage is the only unknown. However, Q_{out} is dependent on both the current and lower lake stages due to backwater effect and constraints imposed by management rules. Since the tailwater (lower lake) stage is unknown a priori in the current time step, an iteration technique is used to converge the estimated and computed stages. The process is accomplished by first estimating Q_{out} from the stages in the last time step, computing the storage change DSTOR from Equation 14, and then updating the stages from the following equation:

$$h_t = h_{t-1} + DSTOR / AREA_{(ht)}$$

<15>

where

 h_t = Stage in current time step in ft msl

 h_{t-1} = Stage in last time step in ft msl

DSTOR= Computed storage change from Equation <14> in acre-ft

 $AREA_{(ht)}$ = Lake surface area in acres from rating equation as a function of h_t

The updated stages are used to revise Q_{out} and DSTOR by Equation 14 and a small number of iterations per time step are needed to converge the stages.

One particular feature of the model is that it can handle missing records. Missing records are signaled by "?" tags in the input files. When a user-specified missing gap is encountered, the model will skip the routing computation, reinitialize the stages to historical at the end of the gap, but continue soil moisture accounting throughout. This provision removes major noise in the input data so that they will not be included in the calibration.

I. Parameter Optimization Procedures

A univariant gradient search procedure is used to aid in the calibration of the watershed parameters. For ungaged watersheds where stream flow data are unavailable. The objective function f(x) is defined as the sum of square deviations of the observed and computed stages of the receiving lakes. For gaged watersheds, f(x) is defined as the sum of square deviations of the logarithmic transformed flows, where x is one of the watershed parameters (SCOEF, HMAX, PCOEF and ROOT) to be adjusted. The adjustment ∂x for x is obtained from the following formula:

$$\partial x = \infty \left[-f(x) / f(x) \right]$$

where

 ∂x = Adjustment for x

x = Parameter value

 One of 52 parameters: SCOEF, HMAX, PCOEF or ROOT in thirteen watersheds

 ∞ = Adjustment factor between 0 and 1

f(x) = Objective function value from model run

= $\sum [h_{obs}-h_{sim}(x)]^2$ or

$$\sum [\log Q_{obs} - \log Q_{sim}(x)]^2$$

 h_{obs} , h_{sim} = Observed and simulated stages of receiving lakes for ungaged watersheds

 Q_{obs} , Q_{sim} = Observed and simulated flows for gaged watersheds

f(x) = Gradient (Partial derivative) of f(x) with respect to parameter x.

Since it is not possible to evaluate f(x) analytically, the gradient (partial derivative) f(x) is determined numerically from the following equation:

$$f(x) = [f(x)-f*(x)]/[x-x^*]$$
 <17>

where

f(x) = Objective function value from current model run

f*(x) = Objective function value from previous model run

x = Parameter value of x at current run

 $= X^* + \partial X^*$

 x^* = Parameter value of x at previous run

 ∂x^* = Adjustment for x in previous run.

Each adjustment iteration requires running the routing model for the entire simulation period (1970 to 1980) one time to renew the objective function value. The new value f(x) and the old value $f^*(x)$ are used to calculate the gradient f(x) by Equation 17, which is then used to determine a new adjustment ∂x for x by Equation 16. Each parameter is adjusted independently by keeping the other parameters constant. To minimize interaction among the watersheds, optimization proceeds from the most upstream watershed to the downstream ones.

VI MODEL USAGE

The model can operate in three different modes, which have been described in detail in Section V. Briefly a "simulation" mode reads in historical hydrologic data directly and is suitable for evaluating the management components of the system. A "calibration" mode reads in the historical rainfall; all other terms are predicted using rainfall as the dependent variable. An optimization option is provided to aid in the calibration of the parameters. A "forecasting" mode is essentially the same as the "calibration" mode except that rainfall is predetermined by the user.

All three routing modes are included in one version of the routing program KROUTE. A brief description of the subroutines in KROUTE is summarized in Table 7. Complimentary to KROUTE are a water budget program KBUDGET and a, now obsolete, plotting program KPLOT. The input and output file requirements for all three programs are listed in Table 8. Files are attached or created dynamically in the programs so that the user need not explicitly manage the files.

The water budget computation program (now subroutine) KBUDGET serves two purposes. One is to verify the historical data, which can be achieved by examining the water budget results. Another is to preprocess the input data files for KROUTE. The water budget function is used only initially and is not required in routine application of the routing program.

Table 7 – Subroutine Functions

KROUTE	This main program initializes data, attaches or creates input data files
	dynamically, and performs routing from lake to lake.
BUILDF	Builds input data file NTAPE5 for "forecasting" run according to user
	specified rainfall scenario and initial stage conditions.
INFLOW	Computes watershed discharges, evaporation, and performs soil moisture
	accounting needed for base flow and direct runoff simulation.
OPT	Performs optimization for watershed parameters by a gradient search
	technique.
	·
STORAGE	Calculates stage area and stage storage relationships from rating
	equations.
DISCH	Computes flow from spillway, culvert, and canal rating equations.
BLOCK DATA	Contains lake, structure, and miscellaneous parameter data needed for
	other subroutines.
	01101 040104111001

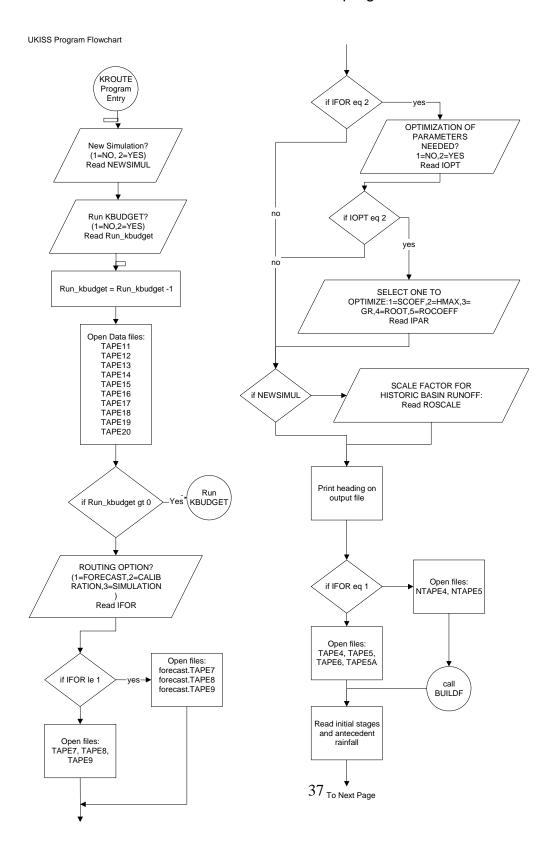

One particular feature of the routing program is that it can handle missing records. Missing records are indicated by "?" tags in the input data records (column 3 of TAPE5 and TAPE6). When a missing gap is encountered, the model will skip the routing computation, initialize the stages to historical, but continue soil moisture accounting throughout. This provision removes major noise from the input data so that they will not be included in the calibration. Missing records or records with errors can be detected by inspecting the water budget results from KBUDGET runs. If a missing gap is small, the gap is filled in by an interpolation or correlation method otherwise a "?" tag is inserted thus allowing the routing program to skip computation.

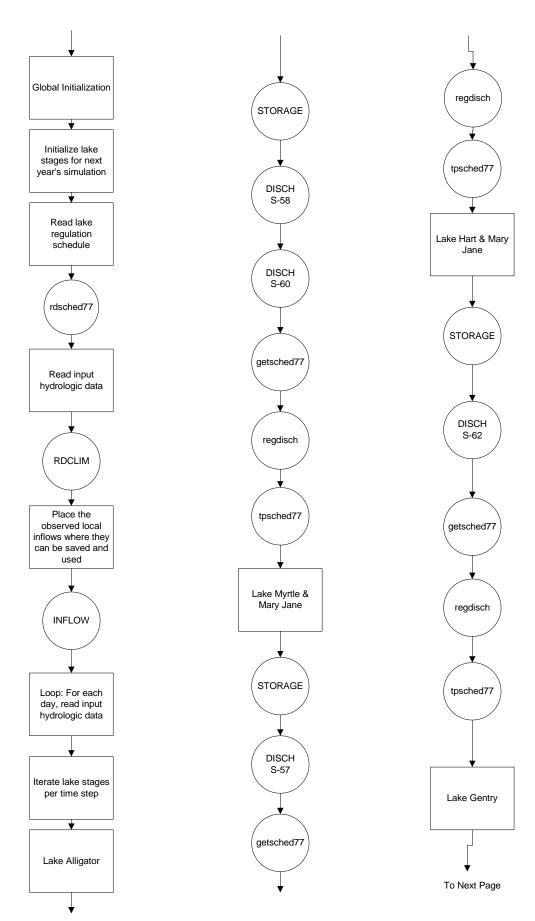

Table 8 – Input and Output Data Files

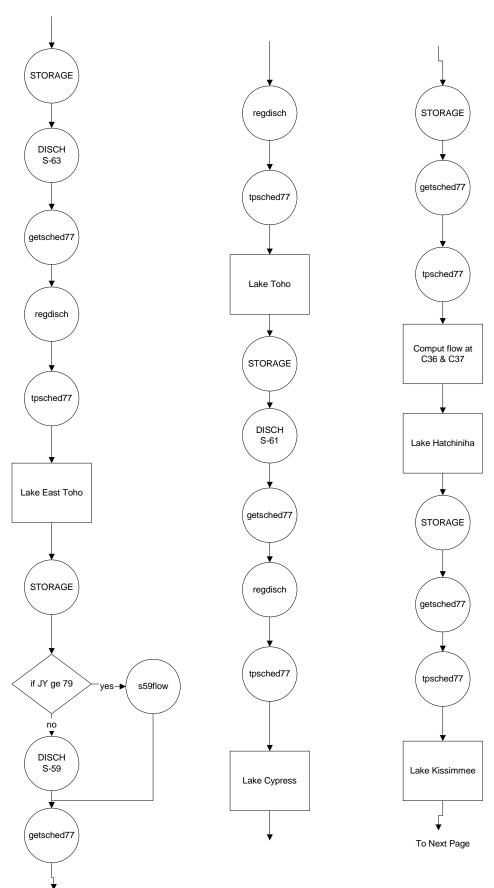

Program	Input Files	Contents	Output Files	Contents
KBUDGET	Tape1	Raw hydrologic data	Tape5	Input data for KROUTE
	Tape2	Raw hydrologic data	Tape6	Input data for KROUTE
KROUTE	Tape4	Regulation schedules	Tape7	Output stages
	Ntape4	Current regulation schedules	Tape8	Output stages
	Tape5	From KBUDGET run	Tape9	Output flows
	Tape6	From KBUDGET run	Tape11-19	Detailed output by lakes
KPLOT	Tape2	Raw hydrologic data		
(superceded)	Tape8	From KROUTE run		
·	Tape9	From KROUTE run		

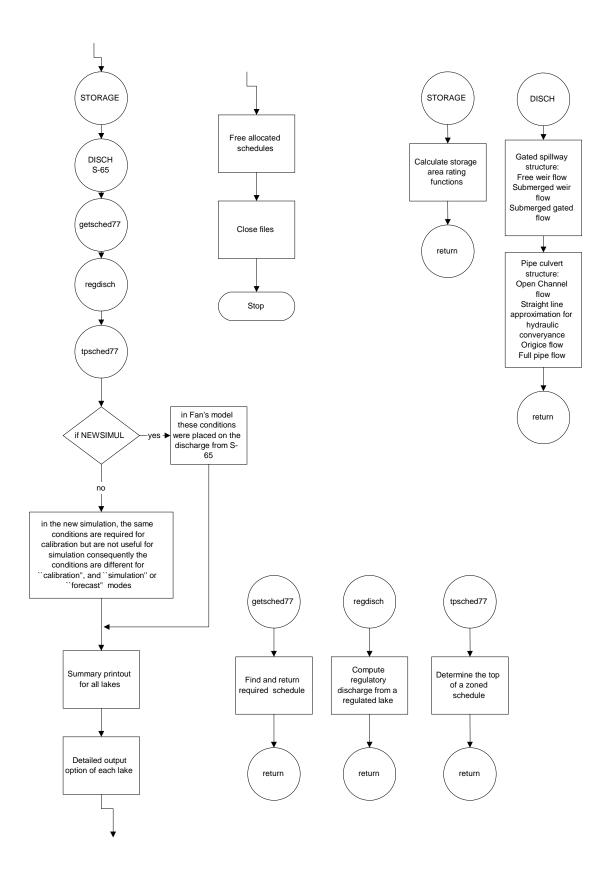

APPENDIX A: MODEL FLOW CHART

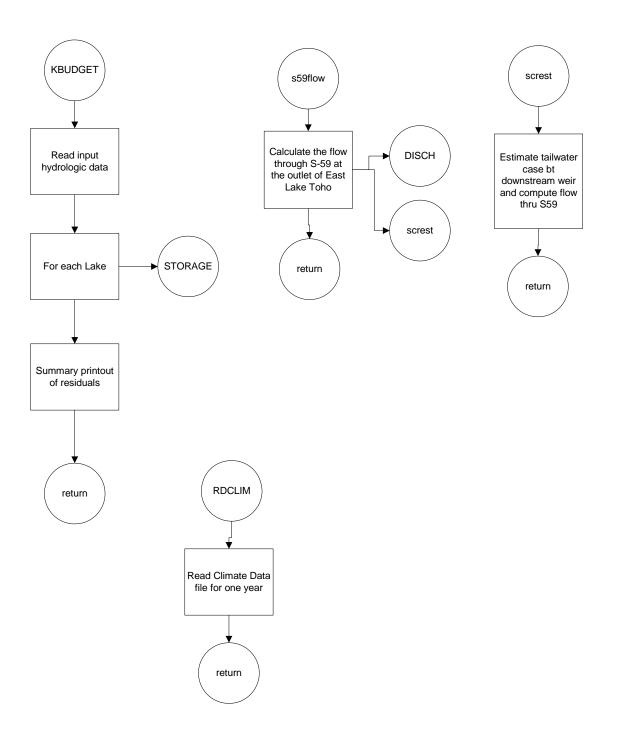

The flow chart for the KROUTE and KBUDGET programs is shown below.

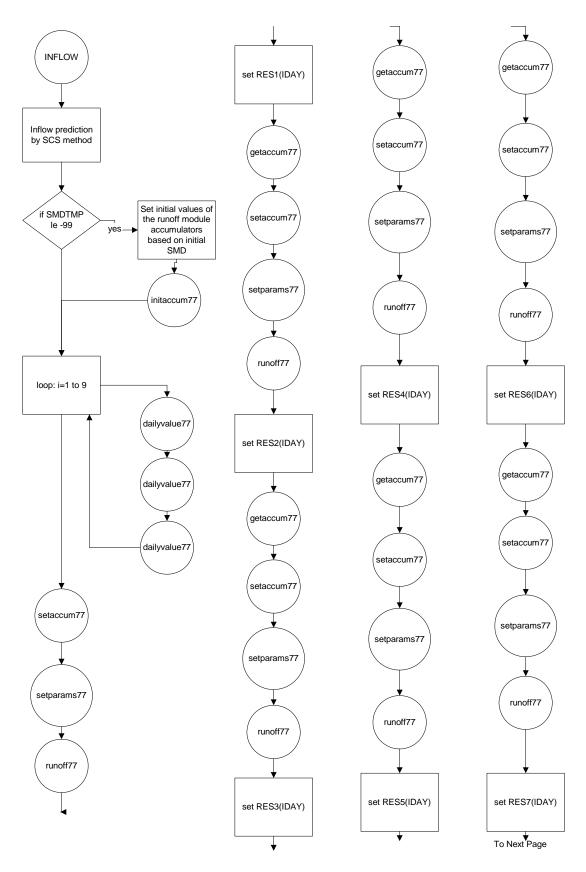

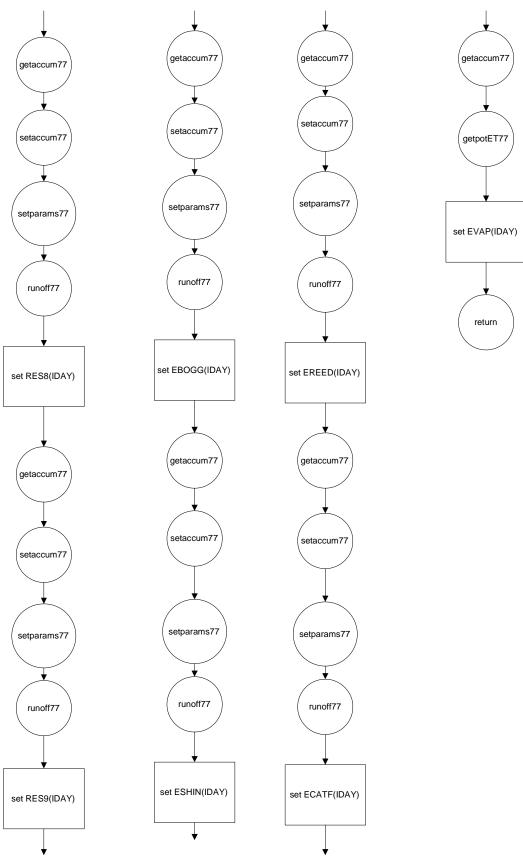

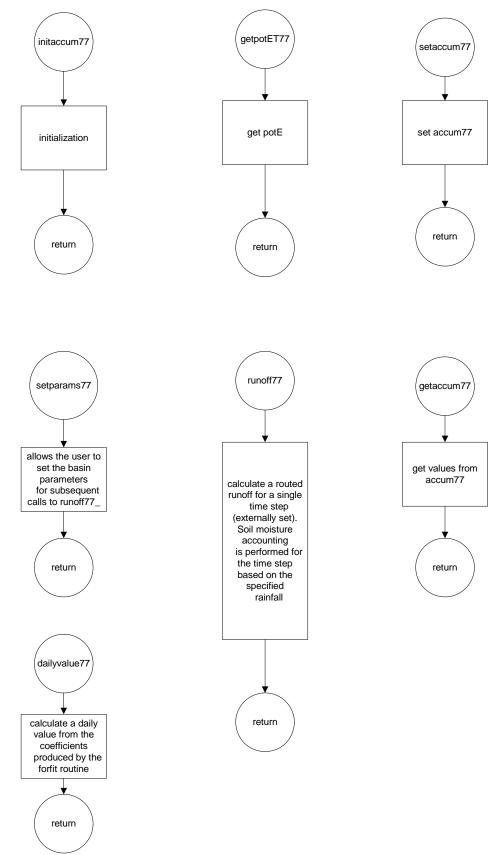

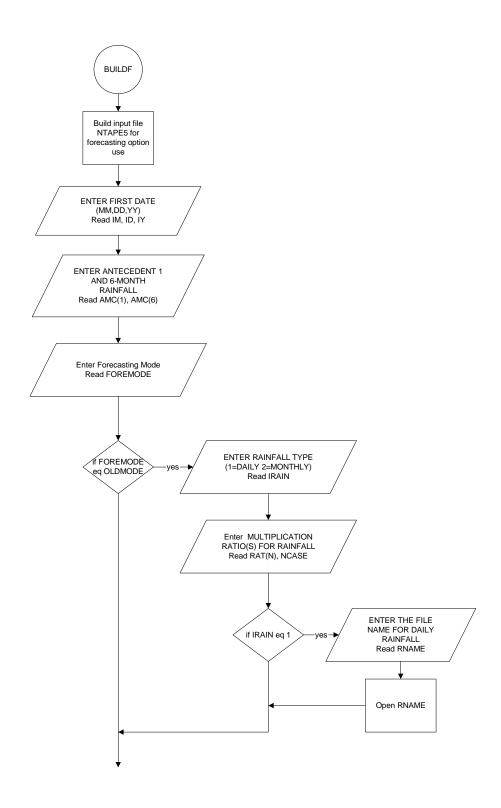

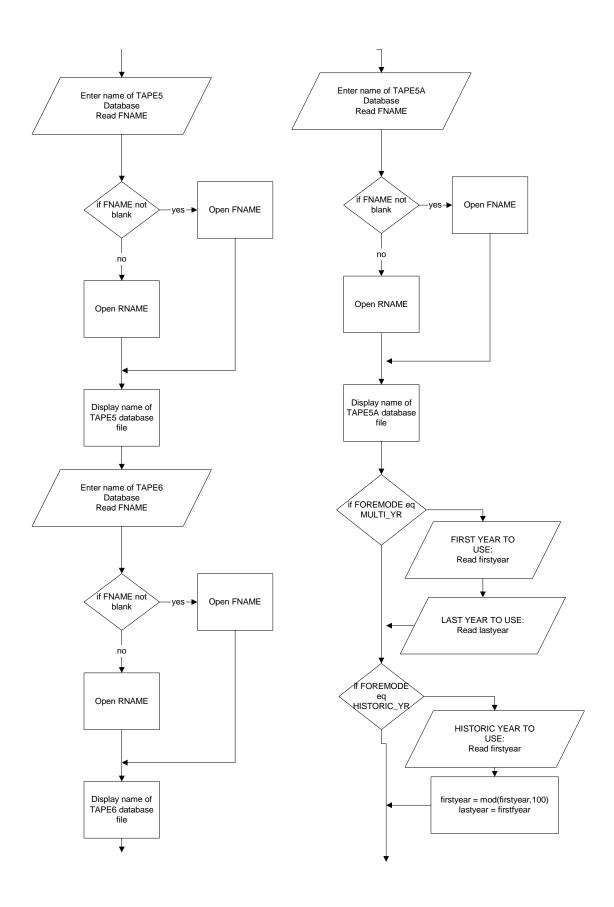

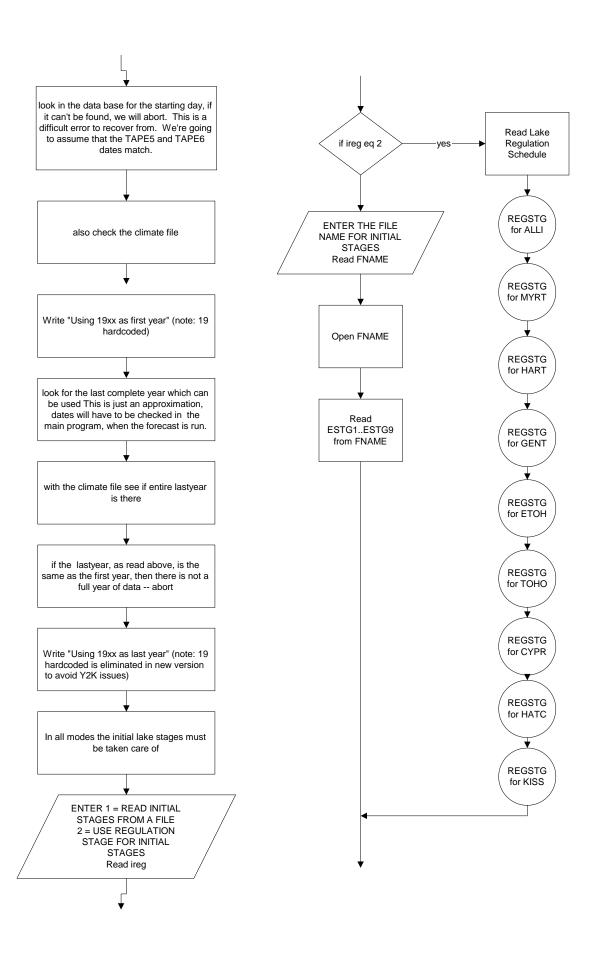

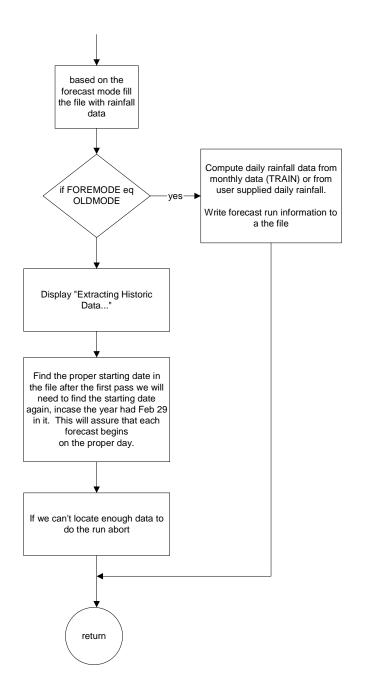

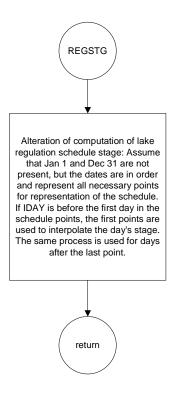

APPENDIX B

Survey data for these lakes was obtained from hand-written Stage/Area/Volume tables. Additional new survey data for Lakes Cypress, Hatchineha, and Kissimmee at two contour elevations (52.5 and 54.0 feet, NGVD is also included. No survey data for Lake Kissimmee is available beyond 54ft NGVD. The "measured area" data used in the table for this lake between elevations 54 and 55 ft is that obtained from the polynomial coefficients.
